The fluctuation-dissipation theorem (FDT), a fundamental result of equilibrium statistical physics, can be violated when a system is taken out of equilibrium. A generalization of FDT has been theoretically proposed for out-of-equilibrium systems; the kinetic temperature entering the fluctuation-dissipation relation (FDR) is substituted by a time-scale-dependent effective temperature. We combine the measurements of the correlation function of the rotational dynamics of colloidal particles obtained via dynamic light scattering with those of the birefringence response to study the generalized FDT in an off-equilibrium Laponite suspension undergoing aging. (i) We find that the FDT is strongly violated in the early stage of the aging process and is gradually recovered as the aging time increases and (ii) we determine the aging-time evolution of the effective temperature, comparing our results with those of previous experiments.

I. INTRODUCTION

The study of the dynamics in nonequilibrium systems is an intriguing and fascinating area of modern physics. There is an obvious interest in the off-equilibrium regime as condensed matter is often found far from ideal equilibrium conditions where “things keep happening on all time scales.”1 A particular class of systems where the out-of-equilibrium status occurs naturally are the so-called glass-forming systems. These systems include, for example, disordered spin systems close to the spin-glass transition, supercooled molecular liquids, and jamming colloidal solutions. In general, the dynamics of these systems is extremely sensitive to change in external parameters so that, when they are a little cooled or densified, the time required to reestablish equilibrium can grow enormously or become infinite (the system never reaches the final equilibrium state). In these situations, an off-equilibrium regime is entered. In this, the average quantities become time dependent and the correlation and response functions depend on two times; in this regime the system is aging.

Correlation functions and response functions are the basic quantities through which one probes the dynamics of a system in many-body statistical physics. These functions are closely related in equilibrium by the fluctuation-dissipation theorem (FDT). The FDT (Ref. 2) establishes a relationship between the correlation function $C_{AB}(t) = \langle A(t)B(t) \rangle$ of the spontaneous equilibrium fluctuations of the dynamic variables $A$ and $B$ and the response function $\chi_{AB}(t) = \langle A(t) \rangle / \eta$, describing the change in the average value of $A$ due to an infinitesimal external field $\eta$ that is coupled to the variable $B$ in the perturbation Hamiltonian,

$$\chi_{AB}(t) = \beta [C_{AB}(0) - C_{AB}(t)].$$

Here $\beta = 1/k_B T$, where $T$ is the kinetic temperature of the system and $A$ and $B$ are variables that have zero mean in the unperturbed case. In this formulation of the FDT, the field $\eta$ introduces a contribution $\delta H = -\eta B$ to the system Hamiltonian, which is switched on instantaneously at $t=0$ and kept constant for $t>0$ as a Heaviside step function. In the following, we will refer to autocorrelation function ($B=A$) and drop the label $AA$ in $C_{AA}(t)$ and $\chi_{AA}(t)$.

Out of equilibrium, the system is nonstationary and time-translational invariance is lost. The correlation and the response become two-times quantities depending also on the aging time $t_w$: $C = C(t_w, t_w + t)$, $\chi = \chi(t_w, t_w + t)$, and the FDT [Eq. (1)] is not expected to hold. The importance of extending the theorem to the nonequilibrium regime has led to the generalized fluctuation-dissipation relation (GFDR).3–5

The generalization of the FDT proposed by Kurchan and Cugliandolo6,7 in the early 1990s can be expressed as follows:

$$\chi(t_w, t_w + t) = \beta \int_{t_w}^{t_w + t} ds X(t_w, s) \langle \delta C(t_w, s) \rangle,$$

where for short times $t$ (i.e., $t/t_w \ll 1$), this equation reduces to the FDT [Eq. (1)] and the system is said to be in a quasi-equilibrium state; for intermediate $t$ ($t/t_w = 1$), the violation function $X(t_w, t)$ quantifies the deviation of the GFDR from the FDT; finally, when $t/t_w \gg 1$, the function $X$ depends on $t_w$ and $s$ only through the function $C$. The violation function can also be interpreted9,10 in terms of an effective temperature $T_{\text{eff}} = T/X$. The latter has complicated behavior for intermediate $t$ values, but in the long-$t$ regime it assumes a value that depends only on the waiting time $t_w$ and one can think of it as “waiting-time-dependent effective temperature.”

The GFDR in out-of-equilibrium systems has been studied theoretically and through computer simulations in spin glasses10,11 and in models for glassy dynamics.12 Later, off-equilibrium molecular-dynamics simulations have given the possibility to perform the same analysis on structural glasses.13–15 Recently, the generalized relation has also been investigated in more exotic systems, such as in the simulations for a glassy protein,16 in self-assembling processes of viral capsids formation and of sticky disks crystallization,17 and in active systems composed of self-propelled particles.18
On the other hand, few experiments have studied the GFDR.\textsuperscript{19–24} Experiments in structural glasses are difficult because it is necessary to simultaneously measure a correlation function of a given variable and the associated response function, and all this in a systems that is \textit{instantaneously} brought out of equilibrium. These difficulties are relaxed in the case of colloidal glasses (or gels or jams) because the associated time scales are much longer and fall easily in the experimentally accessible window.

In this paper, we report an experimental investigation of the generalized FDR in a colloidal systems composed of a water suspension of clay platelets (Laponite), which is \textit{off-equilibrium} when it ages toward the final arrested state (gel or glass, depending on the clay concentration\textsuperscript{25}). We emphasize that the FDT violation and the effective temperature in these colloidal solutions are object of intense debate since the results published so far are controversial (see, for example, Refs. \textsuperscript{21–24} and \textsuperscript{26}). Indeed, previous works on off-equilibrium Laponite suspensions have reported contradicting results in studying the GFDR.\textsuperscript{21–24} Due to the long (with respect to the experimental time scale and to the decorrelation time) aging process of the systems, one can approximate the different measure of fluctuations and response as obtained in a sequence of steady out of equilibrium states.

The anisotropic shape of the clay disk makes it possible to study its reorientational dynamics via the response function. Laponite particles dissolved in water have the form of flat cylinders with a diameter of 25 nm and thickness of about 1 nm. Laponite colloidal particles are good scatterers of visible light and this allow us to rapidly measure the autocorrelation function of the scattered field.

In this work we study the reorientational dynamics of the asymmetric clay platelets, looking at the orientational \textit{correlation functions} via depolarized dynamic light scattering and at the corresponding \textit{response function} via the electric field induced birefringence. Measuring both $C=\chi(t_{in}, t_{in}+t)$ and $\chi=\chi(t_{in}, t_{in}+t)$ at different waiting time during the (days long) aging process, we find that FDT is strongly violated in the early stage of the aging process and is gradually recovered as the aging time increases. Moreover, from the parametric $C-\chi$ plot (the so-called “FDT plot”), we determine the effective temperature and follow its evolution from the high values ($T_{eff}/T \approx 5$) pertaining to young systems toward the equilibrium ($T_{eff}/T = 1$) attained at long waiting time. Our findings confirm the generalization of the FDT to off-equilibrium systems proposed by Cugliandolo and Kurchan \textsuperscript{15} years ago.

\section*{III. CORRELATION FUNCTION}

In a dynamic light-scattering experiment one measures the correlation function of the optical field scattered by the sample. The scattered field can be directly related to the translational and rotational motion of the anisotropic colloids suspended in the solvent.\textsuperscript{28} The colloids’ rotations are related to the second-rank tensor of the optical susceptibility. Specifically, in the VH (depolarized) scattering geometry one measures the autocorrelation function of a variable that depends on the platelet’s orientation,

$$A(t) = \sum_{i} P_{2}[\cos(\theta_{i}(t))],$$

where $P_{2}(x)=(3x^2-1)/2$ is the second-order Legendre polynomial, $\theta_{i}$ is the angle formed by the symmetry axes of the $i$th particle with the polarization vector of the incident field, and the sum is extended over the particles contained in the scattering volume.\textsuperscript{28} This results holds exactly only if the time scale of the rotational dynamics is much faster than the translational one. This assumption was confirmed by comparing the VV (polarized) and VH (depolarized) photon-correlation spectroscopy (PCS) at different waiting times and clay concentration.\textsuperscript{29} The autocorrelation function of $A$ was measured using the VH geometry via PCS. Several autocorrelation functions have been measured during the aging pro-
cess of the sample with a time resolution (1 μs) dictated by the detector (photomultiplier) response. Note that the time is set to zero at the instant at which we stop stirring the colloidal suspension.

IV. RESPONSE FUNCTION

If one applies an external field that tends to align the particles, the system due to the anisotropic platelet’s polarizability becomes birefringent.30,31 If the aligning field is a dc (or low frequency) electric field (Kerr effect), the degree of rotation of a linearly polarized laser beam is proportional to the square of the electric field via a coefficient that is proportional to $A$ [Eq. (3)]. Therefore, the (time-dependent) Kerr response to the switch on of an electric field is proportional to the desired response function (i.e., the response conjugated to the correlation function measured in depolarized PCS). For selected values of the waiting times, the time-resolved response functions and the corresponding correlation functions were measured during the aging process of the Laponite solution. The length of the electric pulses produced sets the dynamic window of our experiment to about 1 ms.

Note that the relaxation time $\tau$ of these functions is always much smaller than the typical waiting time ($\tau \ll t_w$). This means that the time-resolved correlation and response are well-defined quantities although the system is aging. In addition, if any FDT violation can be detected, we expect to find it on a time scale comparable to the relaxation time ($t/\tau \simeq 1$) (Fig. 1).

V. RESULTS AND DISCUSSION

Examples of the measured quantities are shown in the left panel of Fig. 2. The correlation function and the response function are reported as functions of $t$ for different aging times $t_w$.32 For short $t$, the FDT holds while we can see a clear deviation from the FDT for long $t$ where $\chi'/\beta$ does not overlap with $1 - C (t)$ is normalized to $C(0)=1$. When $\chi(t_w-t)+t)/\beta$ is parametrically plotted against $C(t_w-t)+t)$ using $t$ as a parameter (FDT plot), the departure from the $1-C$ line becomes evident (see the right panel of Fig. 2). The deviation from the behavior expected from the FDT reduces its importance as $t_w$ grows, and the time at which $\chi$ and $C$ detaches from each other moves to longer $t$ [see also Fig. 3(a)] where the interested region of the FDT plot has been expanded. In order to quantify this deviation, we introduced a linear fit to the longer-time points in the FDT plot. The slopes ($m$) of these lines are a measure of the effective temperature, $1/m = T_{\text{eff}}/T$.

The $t_w$ dependence of $T_{\text{eff}}$ is reported in Fig. 3(b). $T_{\text{eff}}$ decreases as $t_w$ increases. The linear fit to the long-$t$ region of the FDT plot also defines a characteristic value of the correlation $C$ where the FDT breaks down, the so-called Edwards-Anderson value $q$; this quantity is reported as a function of $t_w$ in Fig. 3(c). Finally, the quantity $q$, defined via $C(t_0)/q_0$ identifies a characteristic time $t_0$ that mark the “starting time” of the violation. $t_0$ is found to move to higher values as the aging time increases [Fig. 3(d)]. It is interesting to compare $t_0$ to the relaxation times $\tau$ of the response and the correlation. We find $\tau$ fitting the correlation and the response with stretched exponentials of the form $\exp[-(t/\tau)^p]$ and $(1-a \exp[-(t/\tau)^p])$, respectively. The response ages faster than the correlation, almost reaching the same relaxation time for the longest $t_w$.

It is important to emphasize that in all models investigated so far for studying the GFDR, the relaxation time grows roughly as the waiting time, $\tau \sim t_w$. The aging process that we study experimentally here does not obey this simple scaling. Indeed, the off-equilibrium (aging time-dependent) relaxation time measured is several orders of magnitude shorter than the typical values of $t_w$. Nevertheless, our results show that the different time scales (the one where the dynamics is at the equilibrium and the one where that is out of the equilibrium) are set by the aging time $t_w$. Indeed, the $\tau(t_w)$ that grows as the sample ages marks the transition from the regime where the FDT holds to another where the FDT is violated.

Finally, we mention that these results show a qualitative behavior that is similar to the one found in dielectric measurements (performed in the frequency domain). $T_{\text{eff}}$ is equal to the bath temperature for short times (at high frequency) while it is higher than $T$ for long times (at low frequency). In addition, the time scale for the deviation of $T_{\text{eff}}$ from $T$ increases as $t_w$ increases (the frequency at which the FDT is violated shifts to lower frequencies).

Although these similarities are intriguing, we stress that some profound differences are also found. First, the relevant
The importance of this deviation reduces as the aging time increases, for the longest waiting time the fitting line overlaps almost perfectly with the pre-

tive temperature and it is found to reduce to the bath temperature as the aging time increases. (c) Waiting-time dependence of the Edwards-Anderson parameter, the characteristic value of the correlation function at which the FDT breaks down. (d) Evolution with time of the characteristic time at which the FDT is violated (O), together with the relaxation time of the correlation function (□) and of the response (∆). The characteristic time for the FDT violation increases as \( t_w \) grows followed by the two relaxation times.

As the dielectric measurement (as the dielectric measurement) give a different result with respect to the various findings obtained via the microrheological measurement mentioned in Sec. I.

In conclusion, by measuring the autocorrelation function of a given variable and the response function of the same quantity in an off-equilibrium (aging) colloidal suspension in the route to the arrested state, we have investigated the generalized fluctuation-dissipation relation. The GFDR applies to the present experiment in the following sense: for short-time scales the FDT is fulfilled, while for long times a clear violation is observed. The characteristic time at which the violation is seen, is always slightly above the aging-time-dependent relaxation time of the measured response and correlation function. Moreover, we observe that the deviation from the standard FDT reduces gradually as the aging time increases and the arrested phase is approached.

FIG. 2. (Color online) (Left) Normalized time-correlation function (○) and response function (□) measured at different aging times (from top to bottom: \( t_w = 90, 125, 225, \) and 1200 min), the solid line represents \( 1 - C \). Note that \( 1 - C \) deviates from \( \chi/\beta \) when the FDT is violated. The importance of this deviation reduces as \( t_w \) increases. (Right) Response function vs correlation function measured at different aging times (○). The black line represents the prediction of the FDT while the color lines represent the linear fits to the points in the off-equilibrium section of the FDT plot. It can be appreciated how these points corresponding to long-time gradu-

tions of the characteristic time at which the FDT is violated, \( \tau_c \), and \( t_0 [s] \) are.

FIG. 3. (Color online) (a) The interesting region of the FDT plots for different aging times: \( t_w = 90, 125, \) and 1200 min (cf. Fig. 2, right panel). (b) The inverse slope of the long-time points of the FDT plot (see Fig. 2) as a function of the aging time (the full line is a guide for the eye). This parameter can be interpreted as an effective temperature and it is found to reduce to the bath temperature as the aging time increases. (c) Waiting-time dependence of the Edwards-Anderson parameter, the characteristic value of the correlation function at which the FDT breaks down. (d) Evolution with \( t_w \) of the characteristic time at which the FDT is violated (O), together with the relaxation time of the correlation function (□) and of the response (∆). The characteristic time for the FDT violation increases as \( t_w \) grows followed by the two relaxation times.

The inverse slope of the long-time points of the FDT plot (see Fig. 2) as a function of the aging time (the full line is a guide for the eye). 2004).
29 See supplementary material at http://link.aps.org/supplemental/10.1103/PhysRevB.81.104201 for preliminary tests verifying the assumption that the rotational dynamics is much faster than the translational one, and tests the linearity of the response function.
32 Here $t_w=0$ is set as the time in which we stop stirring the prepared Laponite suspension. Note that the first measurement of $T_{eff}$ is taken at $t_w=90$ min but we expect $T_{eff}$ at $t_w=0$ to be quite similar to $T_{eff}(t_w=90$ min) since the correlation and response change extremely slowly at the beginning of the aging process.
